Abstract

Belief revision is an operation that aims at modifying old beliefs so that they become consistent with new ones. The issue of belief revision has been studied in various formalisms, in particular, in qualitative algebras (QAs) in which the result is a disjunction of belief bases that is not necessarily representable in a QA. This motivates the study of belief revision in formalisms extending QAs, namely, their propositional closures: in such a closure, the result of belief revision belongs to the formalism. Moreover, this makes it possible to define a contraction operator thanks to the Harper identity. Belief revision in the propositional closure of QAs is studied, an algorithm for a family of revision operators is designed, and an open-source implementation is made freely available on the web.

Keywords: qualitative algebras, belief revision, belief contraction, propositional closure

Introduction

Belief revision is an operation of belief change that consists in modifying minimally old beliefs so that they become consistent with new beliefs (Alchourrón, Gärdenfors, and Makinson 1985). One way to study this issue following a knowledge representation angle is to consider a formalism and to study some belief revision operators defined on it: how they are defined and how they can be implemented.

In particular, it is rather simple to define a revision operator on a qualitative algebra (QA, such as the Allen algebra) by reusing the work of (Condotta et al. 2010) about the related issue of belief merging. The result of such a belief revision is a set of belief bases to be interpreted disjunctively, and which is not necessarily representable as a single belief base: QAs are not closed under disjunction.

This gives a first motivation for the study of belief revision in the propositional closure of a QA: the revision operator in such a closure gives a result that is necessarily representable in the formalism. Another motivation lies in the possibility of defining a contraction operator in this formalism, thanks to the Harper identity.

The first section of the paper contains some preliminaries about various notions used throughout the paper. The next section briefly describes some properties of such a formalism. Finally, an algorithm and an implementation of this algorithm for a revision operator in the propositional closure of a QA are presented with an example.

The research report (Dufour-Lussier et al. 2014) is a long version of this paper including more detailed preliminaries, the proofs and some additional examples.

Preliminaries

Qualitative algebras

Qualitative algebras (QAs) are formalisms that are widely used for representation depending on time and/or on space (Stock 1997). Formulas built upon QAs are closed under conjunction, though the symbol ∧ is not systematically used. Some of the usual notations and conventions of QAs are changed to better fit the scope of this paper. In particular, the representation of knowledge by graphs (namely, qualitative constraint networks) is not well-suited here, because of the propositional closure introduced afterwards.

First, the Allen algebra is introduced: it is one of the most famous QAs and it will be used in our examples throughout the paper. Then, a general definition of QAs is given.

The Allen algebra is used for representing relations between time intervals (Allen 1983). A formula of the Allen Algebra can be seen as a conjunction of constraints, where a constraint is an expression of the form $x \uparrow y$ stating that the interval $x$ is related to the interval $y$ by the relation $r$. 13 base relations are introduced (cf. figure 1); a relation $r$ is either one of these base relations or the union of base relations $r_1, \ldots, r_m$, denoted by $r_1 \mid \ldots \mid r_m$.

For example, if one wants to express that the maths course is immediately before the physics course which is before the English course (either with a time lapse, or immediately before it), one can write the formula:

$$\text{maths} \mathcal{L}_\text{Allen} \text{physics} \quad \wedge \quad \text{physics} \mid \text{english}$$

$L_{\text{Allen}}$ is the set of the formulas of the Allen algebra.

Quantitative algebras in general are defined below, first by their syntax and then by their semantics.
Syntax. A finite set of symbols \( \mathfrak{B} \) is given (with \(| \mathfrak{B} | \geq 2 \)). A base relation is an element of \( \mathfrak{B} \). A relation is an expression of the form \( r_1 \mid \ldots \mid r_m \) \((m \geq 0)\), such that a base relation occurs at most once in a relation and the order is irrelevant (e.g., \( r_1 \mid r_2 \) and \( r_2 \mid r_1 \) are equivalent expressions). The set of relations is denoted by \( \mathfrak{R} \).

A finite set of symbols \( \mathcal{V} \), disjoint from \( \mathfrak{B} \), is given. A (qualitative) variable is an element of \( \mathcal{V} \).

A constraint is an expression of the form \( x \# y \) where \( x, y \in \mathcal{V} \) and \( \# \in \mathfrak{R} \).

A formula \( \phi \) is a conjunction of \( n \) constraints \((n \geq 1)\): \( x_1 \#_1 y_1 \land \ldots \land x_n \#_n y_n \). A constraint of \( \phi \) is one of the constraints of this conjunction. Let \( \mathcal{L}_{QA} \) be the set of the formulas of the considered QA. The atoms of \( \mathcal{L}_{QA} \) are the constraints.

A formula \( \phi \in \mathcal{L}_{QA} \) is under normal form if for every \( x, y \in \mathcal{V} \) with \( x \neq y \), there is exactly one \( r \in \mathfrak{R} \) such that \( x \# y \) is a constraint of \( \phi \). Then, this relation \( r \) is denoted by \( r_{\phi}(x, y) \).

A scenario \( \sigma \) is a formula under normal form such that, for every variables \( x \) and \( y, x \neq y, r_{\sigma}(x, y) \in \mathfrak{B} \). Therefore, there are \(|\mathfrak{B}|^{|\mathcal{V}|\times(|\mathcal{V}|-1)} \) scenarios.

Semantics. The semantics of a QA can be defined classically, thanks to a domain, a variable being mapped into a subset of this domain and a relation being mapped on a relation between such subsets. For Allen algebra, the domain is the set \( \mathbb{Q} \) of rational numbers and, given an interpretation \( I \), a variable \( x \) is mapped to an interval \( I(x) = [a, b] \) of \( \mathbb{Q} \) \((a < b)\). The semantics of each of the basic relations is defined. For example, \( I \) satisfies \( x \preceq y \) if \( b_1 = a_2 \) where \( I(x_1) = [a_1, b_1] \) and \( I(x_2) = [a_2, b_2] \). \( I \) satisfies one of the constraints \( x_k \preceq_y x_k \) for \( k \in \{1, \ldots, m\} \). A formula is consistent (or satisfiable) if there exists an interpretation satisfying each of its constraints. Finally, for \( \varphi_1, \varphi_2 \in \mathcal{L}_{QA} \), \( \varphi_1 \models \varphi_2 \) if, for every interpretation \( I \) satisfying \( \varphi_1 \), it satisfies also \( \varphi_2 \). The research report give more details on this first definition of the semantics.

The semantics can be characterized a posteriori thanks to consistent scenarios.

Let \( \Omega \) be the set of consistent scenarios on the variables of \( \mathcal{V} \). It can be proven that \(|\Omega| \leq |\mathfrak{B}|^{|\mathcal{V}|\times(|\mathcal{V}|-1)/2} \) if \( x \not\equiv y \).
Belief merging is another operation of belief change. Given some sets of beliefs $\psi_1, \ldots, \psi_n$, their merging is a set of beliefs $\Psi$ that contains "as much as possible" of the beliefs in the $\psi_i$’s. Intuitively, $\Psi$ is the conjunction of $\psi'_1, \ldots, \psi'_n$ such that each $\psi_i$ has been minimally modified into $\psi'_i$ in order to make this conjunction consistent. Some postulates of belief merging have been proposed and discussed (Konieczny and Pérez 2002), in a similar way as the AGM postulates.

Belief revision in qualitative algebras

In (Condotta et al. 2010) a belief merging operator is defined that can be easily adapted for defining a revision operator. It is based on a distance between scenarios. Let $\delta$ be a distance function on $\mathcal{B}$. Let $\sigma, \tau \in \Omega$, be two scenarios based on the same set of variables $V$. Then, $d$ is defined by

$$d(\sigma, \tau) = \sum_{x, y \in V, x \neq y} \delta(r(x, y), r'(x, y))$$

One of the possibilities for $\delta$ is the use of a neighborhood graph, i.e. a connected, undirected graph whose vertices are the base relations: $\delta(r, s)$ is the length of the shortest path between $r$ and $s$. Then, the scenarios of the revision of $\psi$ by $\mu$ according to $+d$ are the scenarios of $\mu$ that are the closest ones to scenarios of $\psi$ according to $d$. The set of optimal scenarios is not necessarily representable in $(\hat{\mathcal{L}}_{QA}, \models)$. One solution to address this issue is to consider that the result of revision is a set of scenarios.

Algorithms for implementing this kind of belief revision in QAs are presented in (Dufour-Lussier et al. 2012) and (Hué and Westphal 2012).

Propositional closure of a qualitative algebra

The propositional closure of a QA $(\hat{\mathcal{L}}_{QA}, \models)$ is a formalism $(\mathcal{L}_{QA}, \models)$ defined as follows. $\mathcal{L}_{QA}$ is the smallest superset of $\mathcal{L}_{QA}$ that is closed for $\wedge$ and $\neg$. Then, $\hat{\mathcal{L}}_{QA}$ is closed for $\lor$: $\varphi_1 \lor \varphi_2$ is an abbreviation for $\neg(\neg \varphi_1 \land \neg \varphi_2)$. The entailment relation is based on the consistent scenarios: $\varphi_1 \models \varphi_2$ if $\mathcal{M}(\varphi_1) \subseteq \mathcal{M}(\varphi_2)$, $\mathcal{M}$ being extended on $\hat{\mathcal{L}}_{QA}$ by $\mathcal{M}(\varphi_1 \land \varphi_2) = \mathcal{M}(\varphi_1) \cap \mathcal{M}(\varphi_2)$ and $\mathcal{M}(\neg \varphi) = \Omega \setminus \mathcal{M}(\varphi)$.

Proposition 1 (representability). Every set of scenarios $\Sigma \subseteq \Omega$ is representable in $\hat{\mathcal{L}}_{QA}$. More precisely, with $\varphi = \bigvee_{\sigma \in \Sigma} \mathcal{M}(\varphi) = \Sigma$.

Every formula of $\hat{\mathcal{L}}_{QA}$ can be written in DNF (disjunctive normal form, i.e. disjunction of conjunctions constraints), since it is a propositional closed formalism, but the following proposition goes beyond that.

Proposition 2 (DNF-w/oN form). Every $\varphi \in \hat{\mathcal{L}}_{QA}$ is equivalent to a formula in DNF using no negation symbol.

Belief revision in $(\hat{\mathcal{L}}_{QA}, \models)$

Given a distance function $d$ on $\Omega$, a revision operator on $(\hat{\mathcal{L}}_{QA}, \models)$ can be defined according to equation (1). Indeed, proposition 1 implies that $\{ \omega \in \mathcal{M}(\mu) \mid d(\mathcal{M}(\psi), \omega) = d^* \}$ is representable.

An algorithm for computing $+d$ in $\hat{\mathcal{L}}_{QA}$

The principle of the algorithm is based on the following proposition.

Proposition 3 (revision of disjunctions). Let $\psi$ and $\mu$ be two formulas of $\hat{\mathcal{L}}_{QA}$ and $\{ \psi_i \}_i$ and $\{ \mu_j \}_j$ be two finite families of $\hat{\mathcal{L}}_{QA}$ such that $\psi = \bigvee_i \psi_i$ and $\mu = \bigvee_j \mu_j$.

Let $d^*_{ij} = d(\mathcal{M}(\psi_i), \mathcal{M}(\mu_j))$ for any $i$ and $j$. Then:

$$\psi + \mu \equiv \bigcup_{i,j, d^*_{ij} = d^*} \psi_i + \mu_j$$

Moreover, $d^* = \min_{i,j} d^*_{ij}$

(3)

The algorithm for $+d$ in $\hat{\mathcal{L}}_{QA}$ consists roughly in putting $\psi$ and $\mu$ in DNF-w/oN form then applying proposition 3 on them, using the $+d$ algorithm on $\mathcal{L}_{QA}$ for computing the $\psi_i + \mu_j$’s. More details are given in the research report.

Implementation: the REVISOR/PCQA engine

REVISOR is a collection of several revision engines that are open-source and freely available.1

In particular, REVISOR/QA implements $+d$ in three QAs: the Allen algebra, INDU—an extension of the Allen algebra taking into account relations between intervals according to their lengths (Pujari, Kumari, and Sattar 1999)—and RCC8—a QA for representing topological relations between regions of space (Randell, Cui, and Cohn 1992). Moreover, it is easy to use a different qualitative algebra, by giving in the code some tables (composition table, inverse relation table, and table for the values $\delta(r, s)$ for $r, s \in \mathcal{B}$). The engine is written in Perl, but can be used through a Java library. The worst-case complexity of this implementation is of the order of $O\left(|\mathcal{B}|^{(|V|+1)|V|-1}/2\right)$.

REVISOR/PCQA implements $+d$ on the propositional closures of the QAs $\mathcal{L}_{Allen}$, INDU and RCC8: it actually uses REVISOR/QA and is one of the engines of REVISOR. The worst-case complexity of this implementation is of the order of $O\left(|V|^4|\mathcal{B}|^{(|V|+1)|V|-1}/2\right)$, according to a coarse analysis.

The following example has been executed using REVISOR/PCQA, and is included with the source code. The README file associated with REVISOR/QA on the REVISOR website explains how it can be executed.

This example uses a belief contraction operator. According to (2), a contraction operator $\prec^d$ can be defined that is based on $+d$. Now let us consider the set of beliefs $\psi$ of an agent called Maurice about the dates of birth and death of famous mathematicians. Maurice thought that Boole was born after de Morgan and died before him and that de Morgan and Weierstraß were born the same year (say, at the same time) but the former died before the latter:

$$\psi = \text{Boole} \land \text{De Morgan} \land \text{De Morgan} \land \text{Weierstrass}$$

1http://revisor.loria.fr
where, Boole is the interval of time between the birth and the death of Boole, and so on. Now, Germaine, a friend of Maurice, tells him that she is not sure whether Boole was born strictly after Weierstraß. Since Maurice trusts Germaine (and her doubts), he wants to make the contraction of its original beliefs \( \psi \) by \( \mu \) with

\[
\mu = \text{Boole} \land \text{bi} \land \text{mi} \land \text{oi} \land \text{f} \land \text{d} \; \text{Weierstraß}
\]

The result, computed by \textsc{Revisor/PCQA} in less than one second, is \( \psi \land \text{d} \; \mu \), equivalent to the following formula:

\[
\begin{align*}
&\text{Boole} \land \text{De Morgan} \land \text{Weierstraß} \\
&\lor (\text{Boole} \land \text{Weierstraß}) \land \text{d} \land \text{De Morgan} \\
&\lor (\text{Boole} \land \text{De Morgan}) \land \text{Weierstraß} \\
&\lor (\text{Boole} \land \text{De Morgan}) \land (\text{Weierstraß} \land \text{d} \land \text{De Morgan})
\end{align*}
\]

Actually, the last term of this disjunction corresponds to the reality, provided that the intervals of time correspond to a year granularity: George Boole (1815-1864), Augustus De Morgan (1806-1871), Karl Weierstraß (1815-1897).

In (Dufour-Lussier et al. 2014), other examples of use of \textsc{Revisor/PCQA}, including an analysis of the computing time, are presented. In particular, it is shown that it may be the case that a family of revision problems, albeit formalizable in both \( L_{\text{Allen}} \) and in \( L_{\text{Allen}} \), are solved in much less time in the more expressive formalism \( L_{\text{Allen}} \).

### Conclusion

This paper has presented an algorithm for distance-based belief revision in the propositional closure \( L_{\text{QA}} \) of a qualitative algebra \( L_{\text{QA}} \), using the revision operation on \( L_{\text{QA}} \). This work is motivated by the fact that it gives a revision operation whose result is representable in the formalism, by the fact that some practical examples are easily represented in \( L_{\text{QA}} \) whereas they are quite difficult to represent in \( L_{\text{QA}} \), and by the fact that it makes it possible to define a contraction operator thanks to the Harper identity (which requires disjunction and negation). The preprocessing of the algorithm consists in putting the formulas into a disjunctive normal form without negation. Then, proposition 3, which reduces a revision of disjunctions to a disjunction of the least costly revisions, is applied. \textsc{Revisor/PCQA} is an implementation of this revision operator for the Allen algebra, \textsc{INDU} and \textsc{RCC8}.

A first direction of research following this work is the improvement of the computation time of the \textsc{Revisor/PCQA} system. One way to do it is to parallelize it. A sequential optimization would consist in finding a heuristic for ranking the pairs \((i,j)\), with the aim of starting from the best candidates, in order to obtain a low upper bound of \( d^* \) sooner (hence a pruning of a part of the search trees developed for the computation of \( 1^* \) in \( L_{\text{QA}}, |=| \)).

Another direction of research is to study how other belief change operations can be implemented in this formalism, in particular belief merging (Konieczny et al. 2002) and knowledge update (Katsuno and Mendelzon 1991a).
