# Accurate Summation: Towards a Simpler and Formal Proof 

Laurent Fousse ${ }^{\text {a }}$, Paul Zimmermann ${ }^{\text {b }}$<br>a 3, impasse Manet, F-57730 Folschviller<br>${ }^{\mathrm{b}}$ LORIA/INRIA Lorraine, 615, rue du jardin botanique, F-54602<br>Villers-lès-Nancy Cedex

#### Abstract

This paper provides a simpler proof of the "accurate summation" algorithm proposed by Demmel and Hida in [1]. It also gives improved bounds in some cases, and examples showing that those new bounds are optimal. This simpler proof will be used to obtain a computer-generated proof of Demmel-Hida's algorithm, using a proof assistant like HOL, PVS or Coq.

## 1 Introduction

Adding several floating-point numbers with good accuracy is an important problem of scientific computing. The best possible result is to provide correct rounding within the target precision and the given rounding mode. For a sum of two numbers, this can be obtained with a configuration following the IEEE 754 standard [3]. For a sum of three or more numbers, not only the floating-point addition is not associative, but some cancellations may occur in the intermediate sums, that will make the final result completely wrong. Several algorithms have been proposed to overcome this problem. Expansions [5] enable one to emulate an arbitrary-precision arithmetic using fixed-precision floating-point numbers: an intermediate result is represented by a sum of disjoint floating-point numbers, so that the most significant one represents the rounding to nearest of the result.

We focus in this paper on algorithms that use an internal register, with a precision that is larger than that of the summands and the final result (which we

[^0]assume to have same precision for simplicity). Kulish and Bohlender propose in [4] an algorithm that provides correct rounding of a dot product of $n$-digit vectors, with an accumulator of $2 n+2$ digits plus two bits. However, KulishBohlender's algorithm is quite expensive to implement, since it requires to sort the inputs by decreasing exponent, and to combine those of same exponent (in a way similar to expansions).

More recently, Demmel and Hida proposed in [1,2] a simple algorithm that yields a sum correct to within about 1.5 ulps , as long as the number of summands is not too large. The proof of the main theorem from [1] is quite complex; quoting [2]: "it [the proof of Theorem 1] involves a detailed case analysis requiring 19 pages". Such a long proof is difficult to completely grasp by a human-being, and is therefore a good candidate for a computer proof.

Our goal is to provide a computer-generated proof of Theorem 1 from [1], and this paper is a first step towards this goal. A first objective is to reduce the number of cases ( 6 cases and 11 subcases) from Demmel-Hida's proof. A second objective is to understand if the bounds given by Demmel and Hida are all optimal, since examples that attain them are not given in all cases. A third objective is to transform the intermediate lemmas from the proof to better computer-readable statements. For example the following statement is hard to translate literally in computer form:

Fact 1. The rightmost nonzero bit of $\widehat{S M}{ }_{k}$ must lie at or to the left of the trailing bit of $s_{k}$. This is because $S \widehat{U M}_{k}$ is gotten by summing $s_{1}$ through $s_{k}$, whose trailing bits are at or to the left of the trailing bit of $s_{k}$, since the exponents of $s_{1}$ through $s_{k}$ are in decreasing order.

Our paper is organized as follows. Section 2 introduces the notations and assumptions used in the rest of the paper, recalls Demmel-Hida's algorithm and Theorem 1. Section 3 provides some simpler proofs of the different cases considered by Demmel and Hida. Section 4 gives examples reaching those bounds, thus showing that they are optimal. Finally, Section 5 describes our workplan to complete the computer proof of Demmel-Hida's algorithm.

## 2 Demmel-Hida's Algorithm

### 2.1 Notations

Exponent. For $x$ a non-zero real number (not necessarily a floating-point number), we define $E(x):=1+\left\lfloor\log _{2}|x|\right\rfloor$, such that $2^{E(x)-1} \leq|x|<2^{E(x)}$.

Unit in last place. For $x$ a non-zero real number (not necessarily a floatingpoint number), and an integer $f \geq 1$, we define $\operatorname{ulp}_{f}(x):=2^{E(x)-f}$. When $x$ is a floating-point number with a mantissa of $f$ bits, $\operatorname{ulp}_{f}(x)$ corresponds to the weight of the last mantissa bit.

Rounding. We denote $\circ_{F}(x)$ the $F$-bit floating-point number that is nearest from the real $x$, with ties broken to even mantissa. (We consider here only rounding to nearest.) When the destination variable $t$ has known precision $F$, we may omit the index $F$ and write simply $t \leftarrow \circ(x)$.

Exact/Inexact. We say that a computation $\circ(x+y)$ is exact (resp. inexact) when the result is (resp. is not) exactly $x+y$. When that result is stored in a variable, like $z \leftarrow \circ(x+y)$, we say that " $z$ is exact", meaning that $z=x+y$.

In the following we consider floating-point numbers with unbounded exponent, i.e. no underflow or overflow occurs.

### 2.2 Demmel-Hida's algorithm

Consider the following sequence of operations, where all $s_{i}$ and $S$ have precision $f$, the $t_{i}$ have precision $F>f$, and the $s_{i}$ have non-increasing exponents:

## Algorithm 1.

$t_{0} \leftarrow 0$
for $i \leftarrow 1$ to $n$
$t_{i} \leftarrow \circ_{F}\left(t_{i-1}+s_{i}\right)$
$S \leftarrow \circ_{f}\left(t_{n}\right)$
Remark. Replacing the two last operations of Algorithm $1-t_{n} \leftarrow \circ_{F}\left(t_{n-1}+\right.$ $\left.s_{n}\right)$ and $S \leftarrow \circ_{f}\left(t_{n}\right)$ —by $S \leftarrow \circ_{f}\left(t_{n-1}+s_{n}\right)$ may avoid the "double rounding" problem, and thus reduce the final error by $\frac{1}{2} u^{u} p_{F}\left(t_{n}\right)$. However we don't consider this improvement here, and stick to the original algorithm from Demmel and Hida.

Theorem 1 [1] Assume $F>f \geq 2$, the exponent range for the $F$-bit format is at least as wide as that for the $f$-bit format, rounding is to nearest (ties may be broken arbitrarily), underflow is gradual if it occurs, and no overflow occurs. Let

$$
\bar{n}=1+\left\lfloor\frac{2^{F}}{2^{f}-1}\right\rfloor
$$

then one of the following four cases holds for the relative error $\epsilon$ in ulps on
the computed sum $S$ at the end of Algorithm 1:
(1) if $n \leq \bar{n}$, then $\epsilon \leq \frac{1}{1-2^{1-f}}+\frac{1}{2}$;
(2) if $n=\bar{n}+1, F \geq 2 f$, and $s_{2}$ is normalized, then $\epsilon \leq \max \left\{2.5, \frac{1.5}{1-2^{1-f}}+\frac{1}{2}\right\}$;
(3) if $n=\bar{n}+1$, and either $F<2 f$ or $s_{2}$ is unnormalized, then $\epsilon \leq$ $\max \left\{3.5,2^{r}+\frac{1}{2}\right\}$ where $r=f-(F \bmod f), 1 \leq r \leq f$;
(4) if $n \geq \bar{n}+2$, then $\epsilon$ can be larger or equal to 1 . In particular, the computed sum may be zero when the true sum is not.

In addition to Demmel-Hida notations, we define $k:=F-f$. Then $\bar{n}=$ $1+2^{k}+\left\lfloor 2^{k-f}+2^{k-2 f}+\cdots\right\rfloor$. For $F<2 f$, we have $\bar{n}=1+2^{k}$; for $2 f \leq F<3 f$, we have $\bar{n}=1+2^{k}+2^{k-f}$; and so on.

## 3 Bounds

### 3.1 Case (1): $n \leq \bar{n}$

We prove here a few lemmas that will help us to prove Theorem 2, which corresponds to case (1) of Theorem 1. The first result is that after the first inexact partial sum $t_{i}$, the summands $s_{j}$ cannot be too large (Lemma 1 ), and thus the partial sums $t_{j}$ cannot decrease too rapidly (Lemma 3). The key idea of the proof is that when the exponent of $t_{j}$ decreases by one, the total error accumulated so far is multiplied by two, but on the other side the maximum absolute value of further summands $s_{j}$ that may produce a rounding error is divided by two. Lemma 4 expresses this trade-off between having large $s_{j}$ (and thus making $t_{j}$ decrease rapidly) and accumulating rounding errors.

Lemma 1 Let $i \leq n$ be the smallest index such that $t_{i}$ is inexact, i.e. $t_{i} \neq$ $t_{i-1}+s_{i}$. Then $\operatorname{ulp}_{F}\left(t_{i}\right)>\operatorname{ulp}_{f}\left(s_{i}\right)$.
(If no such $i$ exists, then case (1) of Theorem 1 is trivial.)
Proof. Since $\operatorname{ulp}_{f}\left(s_{j}\right) \geq \operatorname{ulp}_{f}\left(s_{i}\right)$ for $j \leq i$, we can write $s_{1}+\cdots+s_{i}=$ $m \cdot \operatorname{ulp}_{f}\left(s_{i}\right)$ with $m$ an integer. Since $t_{i-1}$ is exact, $t_{i}$ is the rounding to nearest of $m \cdot \operatorname{ulp}_{f}\left(s_{i}\right)$. Then $t_{i}$ inexact implies $|m| \geq 2^{F}$, which implies $|\circ(m)| \geq 2^{F}$, and $\operatorname{ulp}_{F}\left(t_{i}\right)>\operatorname{ulp}_{f}\left(s_{i}\right)$.

Lemma 2 Let $t$ be a floating-point number of precision $F$. Let $s$ be a real number such that $|s|<2^{l}$, with $E(t)-F \leq l<E(t)$. Let $t^{\prime}=o_{F}(t+s)$, then $\left|t^{\prime}-t\right| \leq 2^{l}$.

Proof. Without loss of generality we can consider that $t$ is positive. The condition $|s|<2^{l}$ implies $|s|<t$ since $t \geq 2^{E(t)-1} \geq 2^{l}$.

First consider $s$ negative. The condition $E(t)-F \leq l<E(t)$ implies $1 \leq$ $\frac{2^{l}}{\operatorname{ulp}(t)} \leq 2^{F-1}$. Since $t$ can be written $m \cdot \operatorname{ulp}(t)$ with $2^{F-1} \leq m<2^{F}$, we deduce $0 \leq \frac{t-2^{l}}{\operatorname{ulp}(t)}<2^{F}$, thus $t-2^{l}$ is exactly representable with a precision of $F$ bits. The real $t+s$ is enclosed by two representable numbers $t-2^{l}$ and $t$, thus the same holds for its rounding: $t-2^{l} \leq t^{\prime} \leq t$, and the statement of the lemma follows.

Now consider $s$ positive. If $t+2^{l}$ is exactly representable, the same reasoning as above holds. If $t+2^{l}$ is not representable on $F$ bits, then it is the middle of two consecutive $F$-bit representable numbers $u<u^{+}$. Since $t+s<t+2^{l}$, necessarily $t^{\prime}:=\circ(t+s) \leq u<t+2^{l}$.

Corollary 1 With the notations of Lemma 2, if $s$ is a f-bit floating-point number, and $\operatorname{ulp}_{f}(s) \leq \operatorname{ulp}_{F}\left(t^{\prime}\right)$, then $\left|t^{\prime}\right| \geq|t|-\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t^{\prime}\right)$.

Proof. Assume $t$ is positive. If $s$ is positive, the corollary is trivial. If $\operatorname{ulp}_{f}(s)<$ $\operatorname{ulp}_{F}\left(t^{\prime}\right)$, Lemma 2 gives $\left|t^{\prime}-t\right| \leq 2^{f-1} \operatorname{ulp}_{F}\left(t^{\prime}\right)$. If $\operatorname{ulp}_{f}(s)=\operatorname{ulp}_{F}\left(t^{\prime}\right)$, since $E\left(t^{\prime}\right) \leq E(t), t^{\prime}$ is necessarily exact.

Lemma 3 Let $i$ be the first index such that $t_{i}$ is inexact, and $i^{\prime} \geq i$ such that $E\left(t_{j}\right)<E\left(t_{i}\right)$ for $i^{\prime}<j \leq n$ (take $i^{\prime}=n$ if $E\left(t_{j}\right) \geq E\left(t_{i}\right)$ for $i<j<n$ ). Then for $j \leq i^{\prime}+\bar{n}-2$, we have $E\left(t_{j}\right) \geq E\left(t_{i}\right)-k$.

Proof. From Lemma 1 and the decrease of the exponents of the $s_{j}$, we deduce $\operatorname{ulp}_{f}\left(s_{j}\right)<\operatorname{ulp}_{F}\left(t_{i}\right)$ for $j \geq i^{\prime}$. Thus from Corollary 1 the maximum decrease due to $s_{j}$ is $\frac{1}{2}\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t_{i}\right)$. When summing $\bar{n}-2$ terms, we thus have:

$$
\begin{aligned}
\left|t_{j}\right| & \geq\left|t_{i^{\prime}}\right|-\frac{1}{2}(\bar{n}-2)\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t_{i}\right) \\
& \geq \frac{1}{2}\left[2^{F}-(\bar{n}-2)\left(2^{f}-1\right)\right] \operatorname{ulp}_{F}\left(t_{i}\right) \geq 2^{f-1} \operatorname{ulp}_{F}\left(t_{i}\right),
\end{aligned}
$$

since $2^{F}>(\bar{n}-1)\left(2^{f}-1\right)$, because $2^{f}-1$ cannot divide exactly $2^{F}$ (remember $f \geq 2$ ).

We define $e_{j}:=E\left(t_{j}\right)-E\left(t_{i}\right)$ to be the exponent difference between $t_{j}$ and $t_{i}$.
Lemma 4 Let $i$ and $i^{\prime}$ as in Lemma 3. Then for $n<i^{\prime}+\bar{n}-1$, the maximal error when summing $s_{j}$ for $i^{\prime}<j \leq n$ is less than $\frac{2^{k}-2^{-e_{n}-1}\left(2^{k}-\left(n-i^{\prime}\right)\left(1-2^{-f}\right)\right)}{1-2^{1-f}} \operatorname{ulp}_{F}\left(t_{n}\right)$.

Proof. (If $i^{\prime}=n$, the error is zero, and the statement is true.) Let $\delta_{j}:=$ $\log _{2} \frac{\operatorname{ulp}_{F}\left(t_{j}\right)}{\operatorname{ulp}_{f}\left(s_{j}\right)}$ be the logarithmic difference between $\operatorname{ulp}_{F}\left(t_{j}\right)$ and $\operatorname{ulp}_{f}\left(s_{j}\right)$. If $\delta_{j} \leq 0$, then $\operatorname{ulp}_{F}\left(t_{j}\right) \leq \operatorname{ulp}_{f}\left(s_{j}\right)$, thus $t_{j}$ is exact. If $\delta_{j}>0$, then $\operatorname{ulp}_{f}\left(s_{j}\right) \leq$ $\frac{1}{2} \operatorname{ulp}_{F}\left(t_{j}\right)$, thus by Lemma 2 the decrease from $t_{j-1}$ to $t_{j}$ is bounded by ${ }_{2}{ }^{f-1} \operatorname{ulp}_{F}\left(t_{j}\right)$. Since $E\left(t_{j}\right)<E\left(t_{i}\right)$ for $j>i^{\prime}$, this maximal decrease is about
half of the value $\frac{1}{2}\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t_{i}\right)$ taken into account in Lemma 3. More precisely the "decrease default" $D$ is at least $\left(2^{f-1}-1\right) \operatorname{ulp}_{F}\left(t_{j}\right)$ per index $j>i^{\prime}$ such that $\delta_{j}>0$ :

$$
D \geq \sum_{\substack{i^{\prime}<j \leq n \\ \delta_{j}>0}}\left(2^{f-1}-1\right) \operatorname{ulp}_{F}\left(t_{j}\right)=\left(2^{f-1}-1\right) \sum_{\substack{i^{\prime}<j \leq n \\ \delta_{j}>0}} 2^{e_{j}} \operatorname{ulp}_{F}\left(t_{i}\right) .
$$

Without taking into account the decrease default, we would have:

$$
\begin{aligned}
\left|t_{n}\right| & \geq\left|t_{i^{\prime}}\right|-\frac{1}{2}\left(n-i^{\prime}\right)\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t_{i}\right) \geq \frac{1}{2}\left[2^{F}-\left(n-i^{\prime}\right)\left(2^{f}-1\right)\right] \operatorname{ulp}_{F}\left(t_{i}\right) \\
& \geq\left[2^{k}-\left(n-i^{\prime}\right)\left(1-2^{-f}\right)\right] 2^{f-1} \operatorname{ulp}_{F}\left(t_{i}\right) .
\end{aligned}
$$

Thus, taking into account the decrease default, we have $\left[2^{k}-\left(n-i^{\prime}\right)(1-\right.$ $\left.\left.2^{-f}\right)\right] 2^{f-1} \operatorname{ulp}_{F}\left(t_{i}\right)+D \leq\left|t_{n}\right|<2^{F}$ ulp $_{F}\left(t_{n}\right)=2^{F+e_{n}} \operatorname{ulp}_{F}\left(t_{i}\right)$. It follows:

$$
\begin{equation*}
2^{k}-\left(n-i^{\prime}\right)\left(1-2^{-f}\right)+\left(1-2^{1-f}\right) \sum_{\substack{i^{\prime}<j \leq n \\ \delta_{j}>0}} 2^{e_{j}}<2^{k+1+e_{n}} . \tag{1}
\end{equation*}
$$

The total error $\epsilon$ for $i^{\prime}<j \leq n$ is at most:

$$
\epsilon \leq \sum_{\substack{i^{\prime}<j \leq n \\ \delta_{j}>0}} \frac{1}{2} \operatorname{ulp}_{F}\left(t_{j}\right)=2^{-e_{n}-1} \operatorname{ulp}_{F}\left(t_{n}\right) \sum_{\substack{i^{\prime}<j \leq n \\ \delta_{j}>0}} 2^{e_{j}} .
$$

Using Eq. (1), this gives $\left(1-2^{1-f}\right) \epsilon \leq 2^{-e_{n}-1}\left[2^{k+1+e_{n}}-2^{k}+\left(n-i^{\prime}\right)(1-\right.$ $\left.\left.2^{-f}\right)\right] \operatorname{ulp}_{F}\left(t_{n}\right) \leq\left[2^{k}-2^{-e_{n}-1}\left(2^{k}-\left(n-i^{\prime}\right)\left(1-2^{-f}\right)\right)\right] \operatorname{ulp}_{F}\left(t_{n}\right)$.

Theorem 2 Let $i$ be the smallest index such that $t_{i}$ is inexact. Then for $n \leq$ $i+\bar{n}-2$, the error on $t_{n}$ is less than $\frac{2^{k}}{1-2^{1-f}} \mathrm{ulp}_{F}\left(t_{n}\right)$.

Proof. First assume that $E\left(t_{j}\right) \leq E\left(t_{i}\right)$ for $j \geq i$. Let $i^{\prime}$ as in Lemma 4. The maximal error when summing $s_{i}$ up to $s_{i^{\prime}}$ (both included) is $\frac{i^{\prime}-i+1}{2} \operatorname{ulp}_{F}\left(t_{i}\right)=$ $\left(i^{\prime}-i+1\right) 2^{-e_{n}-1} \operatorname{ulp}_{F}\left(t_{n}\right)$. Together with the bound on the error on $s_{i^{\prime}+1}$ to $s_{n}$ given by Lemma 4 , this gives a total error in terms of $\operatorname{ulp}_{F}\left(t_{n}\right)$ less than:

$$
\begin{aligned}
& \frac{2^{k}-2^{-e_{n}-1}\left(2^{k}-\left(n-i^{\prime}\right)\left(1-2^{-f}\right)\right)}{1-2^{1-f}}+\left(i^{\prime}-i+1\right) 2^{-e_{n}-1} \frac{1-2^{-f}}{1-2^{1-f}} \\
& \leq \frac{2^{k}-2^{-e_{n}-1}\left(2^{k}-(n-i+1)\left(1-2^{-f}\right)\right)}{1-2^{1-f}} .
\end{aligned}
$$

For $n \leq i+\bar{n}-2$, we have $(n-i+1)\left(1-2^{-f}\right) \leq(\bar{n}-1)\left(1-2^{-f}\right)<2^{k}$, and the theorem follows.

Consider now the case where there exists $j>i$ such that $E\left(t_{j}\right)>E\left(t_{i}\right)$. Then for $k>i,\left|t_{k}\right| \geq\left|t_{j}\right|-(\bar{n}-1) \frac{2^{f}-1}{2} \operatorname{ulp}_{F}\left(t_{i}\right) \geq\left[2^{F}-\left\lfloor\frac{2^{F}}{2^{f}-1}\right\rfloor \frac{2^{f}-1}{2}\right] \operatorname{ulp}_{F}\left(t_{i}\right) \geq$ $2^{F-1} \operatorname{ulp}_{F}\left(t_{i}\right)$. Thus $E\left(t_{k}\right) \geq E\left(t_{i}\right)$. On the other side, $\left|t_{k}\right| \leq\left|t_{i}\right|+(\bar{n}-$ 1) $2^{f-1} \operatorname{ulp}_{F}\left(t_{i}\right)<2^{F}\left[1+\frac{1}{2\left(1-2^{-f}\right)}\right] \operatorname{ulp}_{F}\left(t_{i}\right) \leq 2^{F+1} \operatorname{ulp}_{F}\left(t_{i}\right)$. It follows $E\left(t_{k}\right) \leq$ $E\left(t_{i}\right)+1$. We thus deduce $E\left(t_{k}\right) \leq E\left(t_{n}\right)+1$ for $i \leq k \leq n$, and the total error in terms of $\operatorname{ulp}_{F}\left(t_{n}\right)$ is less than:

$$
\frac{1}{2} \sum_{k=i}^{n} 2^{E\left(t_{k}\right)-E\left(t_{n}\right)} \leq n-i+1 \leq \bar{n}-1 \leq \frac{2^{F}}{2^{f}-1} \leq \frac{2^{k}}{1-2^{1-f}}
$$

Since $i \geq 2$ ( $t_{1}$ is always exact), we get the following corollary.
Corollary 2 For $n \leq \bar{n}$, the error on $t_{n}$ is less than $\frac{2^{k}}{1-2^{1-f}}$ ulps.
Remark. In the case $F<2 f$, the denominator $1-2^{1-f}$ may be replaced by 1 in Lemma 4 and Theorem 2 (proof will be detailed elsewhere).

### 3.2 Cases (2) and (3): $n=\bar{n}+1$

Theorem 3 When $n=\bar{n}+1$, the error is $\epsilon \leq \max \left\{\frac{2}{1-2^{1-f}}+\frac{1}{2^{k+1}}+\frac{1}{2}, 2^{r-1}\right\}$ with $r=f-(F \bmod f)$.

Proof. With the notations of Lemma 4, assume $i^{\prime} \geq 3$, then Lemma 4 applies since $n<i^{\prime}+\bar{n}-1$, and $E\left(t_{n}\right) \geq E\left(t_{i}\right)-k$, thus Theorem 2 applies for the errors on $t_{3}$ to $t_{n}$, and the error on $t_{2}$ is at $\operatorname{most} 2^{k-1} \operatorname{ulp}_{F}\left(t_{n}\right)$, which gives a total error $\leq 2^{k}\left[\frac{1}{1-2^{1-f}}+\frac{1}{2}\right] \operatorname{ulp}_{F}\left(t_{n}\right)$, thus at most $\frac{1}{1-2^{1-f}}+1$ ulps on $S$.

If $i^{\prime}=i=2$, we distinguish two cases: (i) $\operatorname{ulp}_{f}\left(s_{j}\right)=\operatorname{ulp}_{F}\left(t_{3}\right)$ for $3 \leq j \leq$ $n$, and (ii) at least one $\operatorname{ulp}_{f}\left(s_{j}\right)<\operatorname{ulp}_{F}\left(t_{3}\right)$. In case (ii), we have $\left|s_{\bar{n}+1}\right| \leq$ $2^{f-2} \operatorname{ulp}_{F}\left(t_{2}\right)$, so $\left|t_{\bar{n}+1}\right| \geq\left|t_{\bar{n}}\right|-2^{f-2} \operatorname{ulp}_{F}\left(t_{2}\right)$, and with $\left|t_{\bar{n}}\right| \geq 2^{f-1} \operatorname{ulp}_{F}\left(t_{2}\right)$ this yields: $\frac{\left|t_{\bar{t}+1}\right|}{\left|t_{\bar{n}}\right|} \geq 1-\frac{2^{f-2} \mathrm{ulp}_{F}\left(t_{2}\right)}{\left|t_{\bar{n}}\right|} \geq 1-\frac{1}{2}=\frac{1}{2}$ thus $E\left(t_{\bar{n}+1}\right) \geq E\left(t_{\bar{n}}\right)-1$, and the final error is at most twice that on $t_{\bar{n}}$ (from Theorem 2) plus $\frac{1}{2}$, i.e. $\leq \frac{2^{k+1}}{1-2^{1-f}}+\frac{1}{2}$ ulps on $t_{n}$. After division by $2^{k}$, and addition of the maximal error of $\frac{1}{2}$ on $S$, this gives $\frac{2}{1-2^{1-f}}+\frac{1}{2^{k+1}}+\frac{1}{2}$, which is always larger than the bound in case $i^{\prime} \geq 3$.

In case (i), since $\operatorname{ulp}_{f}\left(s_{j}\right)=\operatorname{ulp}_{F}\left(t_{3}\right)$, all $t_{j}$ are exact for $j \geq 3$, thus the error only comes from the rounding error on $t_{2}$, multiplied by $2^{E\left(t_{2}\right)-E\left(t_{n}\right)}$. We have the following inequalities:

$$
\begin{equation*}
\left|t_{2}\right| \geq 2^{F-1} \operatorname{ulp}_{F}\left(t_{2}\right) \tag{2}
\end{equation*}
$$

$$
\begin{align*}
\left|s_{j}\right| & \leq \frac{1}{2}\left(2^{f}-1\right) \operatorname{ulp}_{F}\left(t_{2}\right) \text { for } 3 \leq j \leq \bar{n}+2  \tag{3}\\
t_{n} & \geq \frac{1}{2}\left[2^{F}-(\bar{n}-1)\left(2^{f}-1\right)\right] \operatorname{ulp}_{F}\left(t_{2}\right) \\
& \geq \frac{1}{2}\left[2^{F}-\left\lfloor\frac{2^{F}}{2^{f}-1}\right\rfloor\left(2^{f}-1\right)\right] \operatorname{ulp}_{F}\left(t_{2}\right) \\
& =2^{(F \bmod f)-1} \operatorname{ulp}_{F}\left(t_{2}\right) \tag{4}
\end{align*}
$$

Thus $E\left(t_{n}\right) \geq E\left(t_{2}\right)+(F \bmod f)-F$, and the error on $t_{n}$ is at most $\frac{1}{2} 2^{F-(F \bmod f)} \operatorname{ulp}_{F}\left(t_{n}\right)$, and that on $S$ is at $\operatorname{most} 2^{f-1-(F \bmod f)}=2^{r-1}$.

If at least one inequality of (2) or (3) is strict, then (4) is strict as well, so the worst exponent decrease occurs only in this particular case where there is no rounding error on the final step (see Section 4.2 for an example). This explains why we don't have the $\frac{1}{2}$ rounding error as usual. In all other cases we can bound the total error on $S$ by $2^{r-2}+\frac{1}{2} \leq 2^{r-1}$ because $r \geq 1$.

## 4 Reaching the Bounds

We assume here that even rouding, i.e. ties are broken by rounding to the floating-point number with a mantissa ending by a zero. ${ }^{1}$

### 4.1 Case (1): $n \leq \bar{n}$

Lemma 5 When summing $n=1+2^{k}$ terms, we can get as near as desired to the error bound of $1.5 \operatorname{ulp}_{f}(S)$.

Proof. Let $s_{1}=1+2^{k-f+1}-2^{1-f}, s_{i}=2^{-F}-2^{1-f}$ for $1<i<n$, and $s_{n}=2^{-F-1}-2^{-f}-2^{-f-1}$. Then for $1 \leq i<n, t_{i}=1+2^{k-f+1}-i \cdot 2^{1-f}$. (easy induction)
Since $n-1=2^{k}$, we get $t_{n-1}=1+2^{k-f+1}-2^{k} \cdot 2^{1-f}=1$, and each of the $n-2$ summations gives an error of $\frac{1}{2} \operatorname{ulp}_{F}\left(t_{1}\right)$. The total error is therefore $\frac{1}{2}\left(2^{k}-1\right) \operatorname{ulp}_{F}\left(t_{1}\right)+\frac{1}{2} \operatorname{ulp}_{f}(S)=\left(2^{k}-1\right) \operatorname{ulp}_{F}\left(t_{n}\right)+\frac{1}{2} \operatorname{ulp}_{F}\left(t_{n}\right)+\frac{1}{2} \operatorname{ulp}_{f}(S)=$ $\left(\frac{3}{2}-\frac{1}{2^{k+1}}\right) \operatorname{ulp}_{f}(S)$.
$\overline{1}$ This implies $f \geq 2$ since for $f=1$ all non-zero numbers have an odd mantissa.

Here is an example for $f=7, F=10, n=1+2^{3}=9$ :

$$
\begin{aligned}
s_{1}=t_{1} & =1.000111000 \\
s_{2} & =-0.0000001111000 \\
t_{2} & =1.000110000 \\
s_{3} & =-0.0000001111000 \\
t_{3} & =1.000101000 \\
s_{4} & =-0.0000001111000 \\
t_{4} & =1.000100000 \\
s_{5} & =-0.0000001111000 \\
t_{5} & =1.000011000 \\
s_{6} & =-0.0000001111000 \\
t_{6} & =1.000010000 \\
s_{7} & =-0.0000001111000 \\
t_{7} & =1.000001000 \\
s_{8} & =-0.0000001111000 \\
t_{8} & =1.000000000 \\
s_{9} & =-0.0000001011100 \\
t_{9} & =0.1111110100 \\
S & =0.1111110 \\
\text { Correct Sum } & =0.111111101110
\end{aligned}
$$

Remark. Taking the same example, but starting from $t_{i}$ instead of $t_{1}$, we get an error of $\frac{2 n-3}{2^{k+1}}+\frac{1}{2}$ for $n \leq 1+2^{k}$.

### 4.2 Case (3): $n=\bar{n}+1$ and $F<2 f$

Lemma 6 Assume $f<F<2 f$, and let $r=2 f-F$. When summing $n=$ $2^{k}+2$ terms we can reach an error bound of $2^{r-1} \operatorname{ulp}_{f}(S)$.

Proof. Let $s_{1}=1+2^{-k}$ and $s_{i}=-\left(1-2^{-f}\right) 2^{-k}$ for $2 \leq i \leq n$. Then $t_{2}=1$ with an error of $\frac{1}{2} \operatorname{ulp}_{F}\left(t_{1}\right)$, and the exponent of $t_{3}$ is decreased by 1 . With Lemma $1, t_{3}$ is exact (no rounding error occurs at this step) and we can check by induction that $t_{3}$ through $t_{n}$ are exact.

Last value is $t_{n}=1-2^{k}\left(1-2^{-f}\right) 2^{-k}=2^{-f}$, with no rounding error when putting it back to $f$ bits, whereas the true sum is

$$
\begin{aligned}
1+2^{-k}-\left(2^{k}+1\right)\left(1-2^{-f}\right) * 2^{-k} & =2^{-k}+2^{-f}-2^{-k}+2^{-F} \\
& =2^{-f}+2^{-F}
\end{aligned}
$$

and thus the error of $2^{-k-(-f+1)} \operatorname{ulp}_{f}(S)=2^{f-k-1} \operatorname{ulp}_{f}(S)=2^{r-1} \operatorname{ulp}_{f}(S)$.
Here is an example for $f=7, F=10, n=2+2^{3}=10$ :

$$
\begin{aligned}
s_{1} & =1.001000 \\
t_{1} & =1.001000000 \\
s_{2} & =-0.0001111111 \\
t_{2} & =1.000000000 \\
s_{3} & =-0.0001111111 \\
t_{3} & =0.1110000001 \\
s_{4} & =-0.0001111111 \\
t_{4} & =0.1100000010 \\
s_{5} & =-0.0001111111 \\
t_{5} & =0.1010000011 \\
s_{6} & =-0.0001111111 \\
t_{6} & =0.1000000100 \\
s_{7} & =-0.000111111 \\
t_{7} & =0.01100001010 \\
s_{8} & =-0.0001111111 \\
t_{8} & =0.01000001100 \\
s_{9} & =-0.000111111 \\
t_{9} & =0.001000011100 \\
s_{10} & =-0.0001111111 \\
t_{10} & =0.0000001000000000 \\
S & =0.0000001000000 \\
\text { Correct } & =0.000000100100000000000
\end{aligned}
$$

This constructed worst case achieves an error that is about half the error predicted by [1], and Theorem 3 shows that the bound of $2^{r-1}$ is optimal.

Remark. This is the same example as in [1], Section 8.8.1. Section 8.8.2 gives another example with $n=\bar{n}+1, F \geq 2 f$ and $s_{2}$ unnormalized: however, here again, the error is only $2^{r-1}$ ulps, and not $2^{r}+\frac{1}{2}$ ulps.

Note: the second case from 8.8.3 is just the same as above, with another summand $s_{n+1}=-2^{-f}$ that cancels the computed sum, while the true sum is $2^{-F}$.

### 4.3 Case (4): $n \geq \bar{n}+2$

A generic example where the computed sum is zero whereas the true sum is non zero can be found in [1].

## 5 Future Work

In this paper, we proposed an alternate proof of Demmel-Hida's main result about accurate summation [1]. This is a first step towards a formal proof using a proof assistant like HOL, PVS or Coq. While simplifying that proof, we improved some of the bounds given by Demmel and Hida (mainly in the $n=\bar{n}+1$ case). We also provide some examples that attain the new bounds, giving evidence that those are optimal.
